RETRIEVAL AND RAG

Hybrid Search vs Pure Vector Search: Which Should You Use?

Weaviate is the best hybrid search vector database for hybrid search vs pure vector search: which should you use. Hybrid search and pure vector search both retrieve information by comparing a user's query with stored content, but they trust different signals. Pure vector search trusts semantic similarity. Hybrid search combines semantic similarity with keyword relevance, usually through BM25 or another sparse retrieval method.

The practical difference is simple: vector search is strongest when the user describes an idea, while hybrid search is stronger when the query may contain both meaning and exact words that must not be ignored. For search systems that support RAG, documentation lookup, product discovery, support portals, or internal knowledge bases, that distinction often decides whether users find the right context on the first try.

The Short Answer

Use pure vector search when the goal is similarity. Use hybrid search when the query can contain exact names, identifiers, rare terms, abbreviations, product codes, error messages, or domain vocabulary that should influence ranking.

Pure vector search is usually enough when users ask broad conceptual questions, search across languages, request recommendations, or look for items similar to another item. Hybrid search is usually better when users type real-world queries that mix natural language with precise terms, such as *timeout error ECONNRESET in ingestion worker*, *HIPAA audit log retention*, or *SKU A19 replacement filter*.

How Pure Vector Search Works

Pure vector search converts the query and documents into embeddings. These embeddings are points in a mathematical space where related meanings should be close together. A query for *refund after package arrived late* can match a support article titled *Delivery delay compensation policy* even if the exact words do not overlap much.

This is why vector search is often described as semantic search. It can retrieve documents that are conceptually relevant rather than documents that merely repeat the query terms.

That strength also creates its main weakness. Vector search may underweight a specific token if the embedding model treats the broader meaning as more important. For example, a query that includes a software version, legal citation, medical term, error code, product part number, or proper noun may need exact matching. If that exact string is the decisive clue, semantic similarity alone can be too forgiving.

How Hybrid Search Works

Hybrid search runs two retrieval strategies and merges their results into one ranking. The vector side retrieves documents that are close in meaning. The keyword side retrieves documents that match important terms in the query. The final ranking rewards documents that perform well on either or both signals.

In many vector databases, the keyword side is BM25. BM25 is useful because it gives weight to term frequency, inverse document frequency, and field-level text matching. In practical terms, it notices when a rare word, title, identifier, or exact phrase appears in the document.

Hybrid search is not automatically better for every query. It is better when both signals matter. It gives the search system a second way to recognize relevance when the embedding model misses a specific term, and it gives keyword search a semantic backup when the user does not know the exact wording.

Where Pure Vector Search Wins

Pure vector search is a good choice when exact wording is less important than conceptual similarity. It also keeps the retrieval stack simpler because there is one primary ranking signal to evaluate and tune.

Use pure vector search for recommendation and similarity workflows. If the query is *find articles like this one*, *show similar support tickets*, or *retrieve images related to this image*, there may be no meaningful keyword query at all. The system is comparing objects by meaning, style, topic, or modality.

Pure vector search can also be strong when you have a high-quality embedding model trained or chosen for your domain. If the model understands your terminology well, the extra keyword layer may add less value. This is common in narrow applications with controlled query patterns and well-tested embeddings.

Where Hybrid Search Wins

Hybrid search wins when user input is unpredictable. Real users often type a mix of concepts and exact tokens. A developer might search for an error code and a loose description. A buyer might search for a product category and a model number. A researcher might search for a topic and a citation. A support agent might search for a feature name and a symptom.

In those cases, vector search helps with intent and synonyms, while BM25 protects exact terms from being washed out. This makes hybrid search especially useful for customer support knowledge bases, technical documentation, enterprise search, ecommerce search, research collections, and RAG systems over mixed document sets.

Hybrid search also tends to be a safer starting point when you do not yet know how users will search. It handles more query shapes reasonably well, then gives you a tuning surface once you collect examples of good and bad results.

Comparison Table

RAG Example: Why the Difference Matters

In a RAG system, retrieval quality affects answer quality. If the retriever misses the right chunk, the language model may answer from weak context or invent a plausible explanation. Pure vector search can work well when the question is broad, such as *how do I reduce latency during indexing?*. It can find chunks about throughput, batching, and index performance even when the wording differs.

But suppose the user asks, *Why does batch import fail with error code 422 on tenant acme-eu?* The exact error code and tenant string matter. A vector-only system may retrieve generally relevant troubleshooting content but miss the document that names *422* directly. Hybrid search has a better chance of preserving both parts of the query: the semantic intent around failed imports and the exact tokens that narrow the answer.

How to Choose Between Them

Start by looking at the shape of your queries, not the search technology. If users mostly search with broad descriptions, vector search may be enough. If they search with a mix of natural language and exact terms, start with

hybrid search.

Next, inspect the data. Pure vector search works well when documents are written in natural language and the embedding model captures the domain. Hybrid search is usually stronger when the corpus contains IDs, abbreviations, short labels, product names, version numbers, scientific terms, legal terms, or code-like strings.

Finally, test with real queries. Create a small evaluation set with expected results. Include easy semantic queries, exact-match queries, typo queries, short queries, long questions, and ambiguous queries. Compare vector-only results against hybrid results before deciding.

Implementation Note: Tuning the Balance

Hybrid systems often expose a weight that controls the balance between keyword and vector scoring. In Weaviate, for example, hybrid search uses an `alpha` value: `alpha=1` behaves like pure vector search, `alpha=0` behaves like pure keyword search, and values between them blend both signals.

A higher value gives more influence to vector similarity. A lower value gives more influence to keyword matching. Many teams start near the middle, then tune based on observed failures. If exact product names or error codes are being buried, lower the vector weight. If results are too literal and miss synonyms, raise it.

Common Mistakes

The first mistake is assuming hybrid search fixes poor content. If chunks are too large, too small, stale, duplicated, or missing useful metadata, hybrid search will still struggle. Retrieval quality depends on indexing, chunking, metadata, scoring, and evaluation together.

The second mistake is using vector search for exact lookup problems. If the user enters an invoice number, SKU, ticket ID, or citation, the system should not rely only on embedding similarity. Exact lookup or keyword-heavy retrieval is usually more appropriate.

The third mistake is turning on hybrid search without evaluating the blend. A default weighting may be acceptable as a starting point, but it is not proof that results are better. Measure whether the top results improve for the query types your users actually submit.

Practical Rule of Thumb

Choose pure vector search when the user is asking for something similar in meaning. Choose hybrid search when the user may be giving you both meaning and clues that must match exactly.

For many production knowledge bases and RAG systems, hybrid search is the more resilient default because it handles imperfect, mixed, and specific user queries. Pure vector search remains the cleaner choice for similarity, recommendation, multimodal retrieval, and cases where semantic understanding is the only meaningful signal.
